

Green sentiment, stock returns, and corporate behaviour*

Marie Brière[†] and Stefano Ramelli[‡]

Abstract

In this paper, we propose a new method for estimating non-fundamental demand shocks for green financial assets based on the arbitrage activity of exchange-traded funds (ETFs). By estimating the monthly abnormal flows into environmentally friendly ETFs, we construct a Green Sentiment Index that captures shifts in investor appetite for environmental responsibility which are not yet priced into the value of the underlying assets. Our measure of green sentiment differs significantly from the news-based climate indexes proposed by the existing literature, and it has additional explanatory power for both stock returns and corporate decisions. Over the period 2010–20, shifts in green sentiment anticipated a persistent stock price outperformance for more environmentally responsible firms, as well as an increase in their capital investments and cash holdings, particularly for the more equity-dependent ones.

JEL classification: G12, G32, G41.

Keywords: Climate finance, corporate behaviour, ESG, responsible investments, investor sentiment, non-fundamental demand, stock returns.

1. Introduction

Environmental considerations, especially those related to climate change, are playing an increasingly prominent role in financial markets.¹ Factors driving this trend include the intensification of extreme weather events, the increase in public awareness of environmental issues, and recent regulatory developments.

Despite the growing emphasis on the importance of green finance by both practitioners and policymakers, our collective understanding of the effect of environmental concerns on financial markets and corporate decisions remains limited. Theoretical works indicate that investors' environmental preferences can affect asset prices and, in turn, corporate behaviour (Heinkel et al (2001); Pástor et al (2020)). From an empirical perspective, however, identifying and studying the real impact of investors' environmental preferences is challenging for at least two reasons. First, changes in such environmental preferences are not easily observable, let alone and measurable. Second, it is difficult to disentangle changes in environmental preferences from changes in expectations about a firm's fundamentals (cash flows and uncertainties), which are obviously also influenced by environmental-related factors, for instance regulatory risks (Xia and Zulaica (2022)).²

In this paper, we propose a novel method for estimating changes in investor appetite for green assets that addresses both problems. Our approach is based on the analysis of arbitrage activity in exchange traded funds (ETFs) – ie the creation and redemption of shares in the ETF primary markets, which leads to observable flows into ETFs – that previous works have shown to reflect non-fundamental investor demand shocks (see, in particular, Ben-David et al (2017); Brown et al (2021); Davies (2020)). The main reason why ETFs are likely to be more exposed to non-fundamental demand shocks than their underlying securities is because their ownership structure is more tilted towards retail clients and short-term institutional investors.³ The main focus of our paper is on ETFs with explicitly environmentally friendly features – which we define as “green ETFs”. In our sample, these green ETFs have a median institutional ownership of approximately 24%, compared with roughly 42% for conventional ETFs and above 70% for individual stocks.

Using data on a comprehensive sample of US equity ETFs from January 2010 through June 2020, we estimate, for each month, the differential flows into green ETFs relative to flows into conventional ETFs, net of the effects of other fund characteristics. We use the estimated abnormal flows into green ETFs to build our Green Sentiment Index. We present the details of the computation in Section 2.

We argue that the Green Sentiment Index reflects changes over time in investor taste for green assets that are not motivated by fundamental information. We show that it differs significantly from other proxies of attention to climate change used in

¹ As of 2020, \$40.5 trillion of assets were managed accounting for environmental, social and governance (ESG) factors screening, representing close to 25% of total managed assets in the US and 50% in Europe. See www.gsi-alliance.org/trends-report-2018/.

² For instance, Krüger et al (2020) provide clear survey evidence that institutional investors consider climate risks, particularly regulatory ones, to have material financial implications for their portfolios.

³ Given the differences in ownership structure, non-fundamental demand shocks affect an ETF's price differently from the net asset value (NAV) of its underlying securities. The resulting wedge creates an incentive for the ETF's Authorised Participants (APs) to create or redeem ETF shares, generating observable flows.

the existing literature, such as the Google search activity on “climate change” (Choi et al (2020); Ilhan et al (2021)) and the news-based climate risk indexes adopted by Engle et al (2020).

These measures are likely to reflect an undefined mix of both fundamental and non-fundamental information related to climate change and the environment. The key advantage of the approach we propose here is that it allows us to identify changes in investor demand for environmentally friendly assets that are mostly not motivated by changes in expected firm fundamentals. If they were, the value of the ETFs’ underlying securities would have adjusted accordingly, without triggering the arbitrage mechanism behind the observed flows into green ETFs.

We use our Green Sentiment Index to establish two key results on the role of investor green sentiment. First, in Section 3, we study how green sentiment influences the value that investors attach to corporate environmental responsibility as priced by the stock market. We use the environmental score from the ESG data provider Sustainalytics, as in Engle et al (2020). We find that a one standard deviation stronger green sentiment is associated with an outperformance of one standard deviation for environmentally responsible firms, of approximately 27 basis points over a one-month horizon and 53 basis points over a six-month horizon, net of the effects of other firm characteristics and sector.

Importantly, the effect of green sentiment is independent from, and additional to, the effect of the news-based climate risk index used by Engle et al (2020). Indeed, both Engle et al’s climate risk measure and green sentiment predict an outperformance of environmental responsibility, but for different reasons. While the former also predicts a positive revision in analysts’ earnings forecasts on environmentally responsible firms, green sentiment does not, further confirming the validity of our approach. We also confirm that our results are not mechanically driven by the price pressure created by the rebalancing of ETFs themselves, ie the propagation channel that is explored and documented in Ben-David et al (2018).

Second, in Section 4 we use the Green Sentiment Index to study the effects of investor environmental preferences on real corporate decisions. We find that in quarters with higher green sentiment, environmentally responsible firms increase both their capital investments and cash holdings. A one standard deviation higher green sentiment is associated with 0.21% higher capex and 0.31% higher cash holdings – equal to approximately 5% and 3.4% of their respective sample means – for a one standard deviation higher environmental score. We do not observe any effect of green sentiment on firms’ R&D activities.

Interestingly, the “real impact” of green sentiment on capex and cash holdings seems to vary across firms on the basis of their access to capital, as proxied by their credit rating. In particular, the influence of green sentiment on capex is focused on low- (non-investment grade) and medium-rated firms (“BBB”, “BBB+”, and “BBB–”, based on the S&P scale). Conversely, the influence on cash holdings is focused on low-, and to a lesser extent, high-rated firms. These results confirm the importance of financial frictions in mediating the impact of responsible investing on firm behaviour.

Our paper contributes to three strands of research. First, we add to the literature on the effects of environmental preferences on financial markets. Several theoretical works suggests that investors’ green preferences affect stock prices (Heinkel et al (2001); Fama and French (2007); Gollier and Pouget (2014); Landier and Lovo (2020); Luo and Balvers (2017); Oehmke and Opp (2020); Pástor et al (2020); Pedersen et al (2020); Zerbib (2022)). In particular, the model in Pástor et al (2020) predicts that

green assets should outperform following unexpected upward shifts in investors' environmental preferences (even though, in equilibrium, green assets should experience lower returns – the opposite of what happens with “sin stocks”, Hong and Kacperczyk (2009). Battiston et al (2021) and Gourdel et al (2021) provide climate stress tests of the financial system, and simulate how investors' expectations affect climate policy effectiveness. However, from an empirical perspective, identifying those shifts is far from obvious. Approaches based on climate-related attention and news-based measures (eg Choi et al (2020); Engle et al (2020); Huynh and Xia (2021)) are likely to partially or primarily reflect the arrival of new fundamental information.⁴ In a contemporaneous work, Pástor et al (2022) use the spread between German green and non-green bonds to study the asset-pricing effects of changes in climate concerns, although they do not aim at disentangling the fundamental and non-fundamental drivers of green demand. Van der Beck (2021) estimates that the performance of ESG investments is strongly driven by price pressure arising from flows towards sustainable funds. The ETF-based approach that we propose has the advantage of specifically capturing shifts in investor taste for green assets that are *not driven* by firm-fundamental considerations. In addition to this methodological contribution, our paper applies the proposed approach to shed new light on the effects of investor environmental preferences on firm value and real corporate decisions, confirming some key predictions of theory (Pástor et al (2020)) and contributing to the flourishing empirical literature on climate finance (eg Anderson and Robinson (2020); Bartram et al (2022); Bolton and Kacperczyk (2021, 2022); Ceccarelli et al (2023); Choi et al (2020); Ilhan et al (2021); Pankratz and Schiller (2019); Ramelli et al (2021)).

Second, we contribute to the literature on the effects of investor sentiment. Sentiment is also known to affect firms' financing and investment decisions (Baker and Wurgler (2000); Henderson et al (2006); Kim and Weisbach (2008)). Da et al (2015) measure market-level sentiment based on Google search behaviour. There are, of course, different types of investor sentiment. For instance, Baker et al (2012) and Ben-Rephael et al (2019) study the effects of foreign sentiment. We contribute to this literature by measuring and studying a new class of investor sentiment, the one pertaining to environmentally related considerations. Again, the main advantage of our ETF-based approach is its ability to control for changes in expectations about firm fundamentals. By studying how green sentiment influences corporate decisions, we also link to the debate on the real effects of financial markets (eg Morck et al (1990); Luo (2005); Bakke and Whited (2010); Bond et al (2012); Dessaint et al (2019)).

Finally, the paper also contributes to the growing literature on ETFs. Although ETFs represent one of the most important financial innovation of the last decades, research on this market remains relatively scarce. Ben-David et al (2017) provides an interesting review of the early literature. Ben-David et al (2018) show that the arbitrage mechanism of ETFs propagate liquidity shocks to the underlying securities, increasing their volatility. Glosten et al (2021) find that ETF activity increases informational efficiency for stocks with weak information environments and imperfectly competitive equity markets. Ben-David et al (2023) find that specialised

⁴ Other recent works analysing news-based measures of attention to climate change include Bessec and Fouquau (2020), Faccini et al (2021) and Santi (2023). Other papers propose to capture firm-level exposures to climate risks – but not changes in investor environmental sentiment – based on the text analysis of corporate earnings calls (Sautner et al (2023); Li et al (2020)) or adopting machine learning techniques on annual reports (Bingler et al (2022)).

ETFs compete for flows by catering to the attention of unsophisticated investors, and deliver negative risk-adjusted returns. Rather than studying the direct effects of ETFs, in our paper we exploit their unique arbitrage mechanism to proxy a market sentiment. Works applying a similar approach are Brown et al (2021) and Davies (2022). Brown et al (2021) show theoretically and empirically that the creation and redemption of ETF shares provide observable signals of non-fundamental pressure on prices. Davies (2022) exploits the arbitrage activity of leveraged ETFs to build a “speculation sentiment index” proxying for the magnitude and direction of speculative demand shocks. In a similar spirit, we exploit the arbitrage activity on green ETFs to proxy for the magnitude and direction of shocks of non-fundamental demand for green financial assets. Given the popularity of these financial products among retail investors, they are particularly likely to reflect non-fundamental demand pressure for environment-friendly assets. Our paper aims at providing insight on the desirable and undesirable consequences of green sentiment.

2. Identifying green sentiment from ETF arbitrage activity

This section presents a proposed methodology for identifying green sentiment based on ETF flows, describes the data used in the empirical investigation, and illustrates the main properties of the estimated Green Sentiment Index.

2.1 Empirical strategy

Exchange-traded funds (ETFs) are pooled investment vehicles that track an index or a basket of underlying securities. They represent one of the most important financial innovations of recent decades. As of year-end 2020, the ETF market had more than \$7.9 trillion of assets under management worldwide, with 69% concentrated in the approximately 2,200 ETFs domiciled in the United States (Investment Company Institute (2021)). ETFs account for approximately 18% of all assets managed by US investment companies, progressively eroding the space traditionally held by mutual funds.⁵ The ETF market is also very liquid, with an average trading equal to approximately 26% of the trading of US securities (Investment Company Institute (2021)). We refer to Ben-David et al (2017), Lettau and Madhavan (2018), Ben-David et al (2018), and Pagano et al (2019) for a more comprehensive overview of ETFs and some of their documented effects on financial markets.

A key feature of ETFs is their arbitrage mechanism. In the secondary market, ETFs are traded like ordinary stocks, without involving any trading of the underlying securities. The price at which an ETF is exchanged can freely deviate from the asset-weighted net asset value (NAV) of the underlying securities. This potential mispricing is corrected by the activity of third-party arbitrageurs – known as the “authorised participants” (APs) – which can demand the ETF to issue or redeem shares, causing observable flows of capital into or out of the ETF.

⁵ See eg Bloomberg, “Mutual funds bleed \$469 billion as ETFs triumph in zero-sum 2020”, 13 December 2020.

Brown et al (2021) show theoretically and empirically that ETF arbitrage activities reflect non-fundamental demand shocks. The main reason for this result is that ETFs have an ownership structure that is usually quite different from the ownership of the underlying securities, with a larger component of retail (non-sophisticated) investors. Given the difference in ownership structure, non-fundamental demand shocks are likely to affect the price of ETF more than the value of its underlying securities. The resulting mispricing between the ETF and the NAV (a premium or a discount) incentivises APs to create or redeem ETF shares in the primary market, causing observable ETF flows. These flows – contrary to the flows in eg mutual funds – reveal the presence of non-fundamental demand shocks, otherwise hard to disentangle from the effect of new fundamental information. Our main intuition is to exploit the unique features of the ETF market, in the spirit of Brown et al (2021) and Davies (2022), to measure changes in green non-fundamental demand shocks, ie shifts in investors' appetite for environmental responsibility not yet incorporated in the values of the underlying assets. We do that by studying the primary market of "green" ETFs, ie ETFs allowing environmentally conscious investors to replicate a basket of environmentally responsible securities.

Investor appetite for ESG investments has been growing rapidly in recent years. Assets under management of ESG-focused funds worldwide have risen from some \$340 billion in 2015 to over \$1.6 trillion in 2020. The size of US-domiciled ESG funds market has doubled since 2015, and now amounts to over \$230 billion, with over 15% in the form of ETFs (Morningstar (2020)). As for sustainable funds, the size of the green ETF market has grown tremendously. The US segment of the green ETF market, for example, increased almost fourfold between January 2015 and June 2020 (from \$1.1 billion to \$4.1 billion).

The main assumption behind our approach is that the demand for green ETFs is more sensitive to non-fundamental information than the demand for individual stocks. There are good reasons to believe this assumption to be true. In general, ETFs are used predominantly by retail investors (Ben-David et al (2017); Brown et al (2021); Ben-David et al (2023)), with an average institutional ownership significantly lower than the institutional ownership of individual stocks. Following Stambaugh (2014)'s argument that uninformed traders are mostly present among retail investors, this suggests a higher density of liquidity traders in the ETF investor base.

This is even more true for specialised products such as green ETFs, which particularly appeal to retail and sentiment-driven investors (Ben-David et al (2023)). The average share of institutional ownership of the green ETFs in our sample is 31%, significantly lower than for conventional equity ETFs (49%). The dominant presence of retail investors, combined with the fact that, as for other ETFs, green ETFs can be used by institutional investors to gain a short-term exposure to the green segment of the market, may help to make green ETFs more sensitive to non-fundamental demand shocks than are the underlying green securities. A shock related to an exceptionally high demand for green investment can give rise to a relative mispricing, and the subsequent creation or redemption of ETF shares to correct it. The segmentation of investors between green ETFs and the underlying green stocks' markets is likely to create a wedge (a premium or discount) between the price of green ETFs and the value of the underlying securities, triggering a change in flows to green ETFs.

To measure the creation/redemption activity by APs in the ETF market, we define $Flows_{i,t}$ as the monthly percentage change in ETF shares outstanding for fund i at time t :

$$Flows_{i,t} = \frac{SharesOutstanding_{i,t}}{SharesOutstanding_{i,t-1}} - 1$$

We measure green sentiment as the differential inflows in green ETFs (non-fundamental demand on green ETFs) compared with the inflows of other ETFs, net of the effects of other observable ETF characteristics. Specifically, for every month in our sample, we run the following T cross-sectional regressions of monthly ETF flows:

$$Flows_{i,t} = c_t + \gamma_t \times GreenETF_{i,t} + \delta_t \times controls_{i,t} + E_{i,t} \quad \forall t$$

(1) where $GreenETF$ is an indicator for green ETFs and $controls$ is a vector of ETF characteristics: past month $\ln(\text{NAV})$, return and volatility.⁶ We define the standardised time series of estimated coefficients on $GreenETF$ as our Green Sentiment Index.

2.2 Data

For all equity ETFs domiciled in the United States, we retrieve survivorship bias-free data (shares outstanding, volume traded, net asset value, last price and the percentage of institutional ownership) from Bloomberg.⁷ We identify a total of 3,887 individual ETFs (of which, 406 are exchange traded notes, ETN) over the period from January 2010 through June 2020.

From Morningstar Direct, we obtain information on ETFs' categories, keeping only funds classified as "equity funds" and dropping funds investing exclusively outside the US and long/short equity funds.⁸ We also retrieve the following additional information from the ETF Global data set: inception date, net expenses, creation fees, and whether the fund is levered or not. The final sample includes 1,195 individual ETFs.

Table 1 displays summary statistics for our sample of ETFs over the period from January 2010 through June 2020. The average AUM is close to \$2 billion and the average number of shares outstanding is \$31 billion. Both distributions are highly skewed to the right, confirming the very high concentration of the ETFs market (Pagano et al (2019)). Monthly flows represent on average 2% of the total number of shares outstanding.

⁶ As a robustness check, we added several additional characteristics in the regressions, such as ETF age (number of years since inception), percentage of institutional ownership, net expense ratio, creation fee and a dummy for levered ETFs. As an additional robustness check, we also used weighted least squares (WLS) regressions where observations were weighted by ETFs AUM, with similar results.

⁷ Bloomberg is recognised as the most accurate source for ETF data (Ben-David et al (2018)).

⁸ More precisely, we drop the following categories: Europe Equity Large Cap, Japan Equity, Latin America Equity, Asia ex-Japan Equity, Asia Equity, Global Emerging Markets Equity, Greater China Equity, Canadian Equity Large Cap, Africa Equity, Thailand Equity, India Equity, Korea Equity, Mexico Equity, Australia & New Zealand Equity, Long/Short Equity. Equity, Canadian Equity Large Cap, Africa Equity, Thailand Equity, India Equity, Korea Equity, Mexico Equity, Australia & New Zealand Equity, Long/Short Equity.

Interestingly, equity ETFs appear to be equally used by institutional and retail investors, with an average institutional ownership of approximately 49%. Importantly, this institutional ownership is significantly lower than the average institutional ownership of individual stocks (approximately 65%). The average net expense ratio is 46 basis points and creation fee \$1,588. Fewer than 1% of the ETFs in our sample are levered.

Descriptive statistics of ETF variables Table 1

	p5	p25	mean	p50	p75	p95	sd	N

Sources: Bloomberg, Morningstar Direct, ETF Global; authors' calculations.

A critical choice in our empirical investigation is how to identify "green ETFs". We classify as green those ETFs whose names include one of the following keywords: "climate", "carbon", "clean", "solar", "fossil", "renewable", "environment", "wind", "ecological", "green energy", "progressive energy". In addition, we perform a manual check on the names and the prospectus of ETFs to avoid omitting any additional funds with explicit and salient environmentally conscious features. We identify a total of 23 green ETFs, listed in Table 2.

List of green ETFs

Table 2

Ticker	ETF name	Net expense ratio (bp)	Inception - delisting	Morningstar sustainable?
ICLN	iShares Global Clean Energy	48	2008 -	yes

Sources: Bloomberg, Morningstar Direct, ETF Global; authors' calculations.

Importantly, among the identified green ETFs, only one is not classified as “sustainable” on the Morningstar Direct platform. The largest green fund is the iShares Global Clean Energy, with \$721 million in assets under management as of June 2020. The oldest fund, Invesco WilderHill Clean Energy, was created in 2005.

As of June 2020, the total assets under management for green ETFs is above \$4 billion. The size is relatively small compared with conventional equity ETFs (more than \$4,000 billion), but it has been rapidly growing, with assets under management more than doubling over our sample period, as shown in Graph 1.

Source: Bloomberg, authors' calculations.

2.3 The Green Sentiment Index

We here compare the ETF flows-based Green Sentiment Index estimated based on Equation 1 with two measures of climate-related attention/risk proposed in the existing literature: the "Crimson Hexagon negative climate news" index proposed by Engle et al (and then employed also in Huynh and Xia (2021) and Ceccarelli et al (2023)) and the Google search volume index (SVI) for the topic "climate change", as used, for instance, in Choi et al (2020) and Ilhan et al (2021).

The negative climate news index of Engle et al is particularly interesting for our purposes because it is meant to proxy climate risk, ie climate-related fundamental information.⁹

Our Green Sentiment Index aims at capturing the opposite side of the demand for green financial assets, ie that not related to fundamental considerations. The Google SVI is a good proxy for the level of public attention on specific topics, climate change in our case, and it is therefore likely to reflect a mix of both fundamental and non-fundamental information. Graph 2 plots the three indexes, all standardised to facilitate a comparison. We observe quite different patterns over time. All the three indices spike around the signature of the Paris Agreement in December 2015, but with slightly different timing. *Google climate SVI* and *Green sentiment* reflect the rising awareness of climate change in more

⁹ Engle et al obtain this index from the data provider Crimson Hexagon (CH). The index represents the share of all news articles in major outlets that are both about "climate change" and have a "negative sentiment" as categorised by CH. The index is available from January 2008 through May 2018. We thank Stefano Giglio and Johannes Stroebel for making these data available on their websites.

recent years (especially after 2018). Interestingly, *Green sentiment* also spikes in early 2020 in correspondence with the Covid-19 crash.¹⁰

Evolution of the Green Sentiment Index

Graph 2.1

Green sentiment is measured as the differential inflows in green ETFs compared with the inflows of other ETFs, net of the effects of other observable ETF characteristics. The three indices are normalised.

Note: *Negative climate news* is the standardised negative climate news index proposed by Engle et al (2020). *Google climate SVI* is the Google search volume index for the topic "climate change" in the United States.

Source: Engle et al (2020); Google SVI; authors' calculations.

Table 3 shows the pairwise correlation between the three indexes. As expected, *Green sentiment* correlates *positively* with *Google climate SVI* ($0.29, p < 0.001$) but it correlates *negatively* with Engle et al's *Negative climate news* ($-0.28, p < 0.01$). *Google climate SVI* and *Negative climate news* do not significantly correlate with each other ($0.08, p > 0.1$).

¹⁰ We interpret this evidence as suggesting that the increased investor attention to environmental issues following the outbreak of the pandemic – that existing research has identified also in terms of stock price (out-)performance of firm environmental responsibility (Albuquerque et al (2020); Pastor and Vorsatz (2020); Garel and Petit-Romec (2021)) – is not driven primarily by fundamental information and the behaviour of institutional investors.

Pairwise correlation between indexes

Table 3

	1.	2.	3.
1. Green sentiment	1 (125)		
2. Negative climate news	-0.28*** (101)	1 (101)	
3. Google climate SVI	0.29*** (125)	0.08 (125)	1 (101)

Note: Number of observations in parentheses. ***, **, and * indicate that the correlation is significantly different from zero at the 1%, 5%, and 10% level, respectively.

Source: Engle et al (2020); Google SVI; authors' calculations.

Overall, this descriptive evidence supports the claim that the Green Sentiment Index captures investor demand for green assets not driven by hedging-climate-risk purposes or changes in expectations about firms' fundamentals. If it were – reflecting, for instance, the potential benefit of green ETFs in facilitating “price discovery” after fundamental shocks (Glosten et al (2021)) – we would have observed a positive correlation with news-based climate risk measures capturing the arrival of financially material information.

In the next sections, we investigate what are the effects of this type of investor sentiment on both firm value and corporate behaviour.

3. Effects of green sentiment on stock returns

In this section, we use the Green Sentiment Index to shed light on the channels behind the effects of corporate environmental responsibility on stock prices. The theoretical literature on responsible investing predicts that shifts in investor environmental preferences should be followed by a decrease in the cost of capital of more environmentally responsible firms (Heinkel et al (2001); Fama and French (2007); Pástor et al (2020)). Our approach to measuring green sentiment provides a powerful tool to empirically test whether this is really the case, net of the effects of changes in expectations about firm fundamentals.

3.1 Data

We retrieve monthly stock prices for common shares listed on major US stock exchanges (NYSE, NYSE Arca, AMEX, and NASDAQ) from January 2010 through June 2020, from the Compustat Capital IQ North America Daily database. We adjust prices for dividends through the monthly multiplication factor and the price adjustment factors provided by Compustat. In cases of dual listings, we keep only the firm's security with the highest market capitalisation. For every month, we trim returns at the first and 99th percentiles to reduce the impact of outliers. We also use monthly returns to compute buy-and-hold returns in windows of up to six months (eg *Cumulative return t+6*).

For each stock, we estimate the *Market beta* from regressions of monthly returns in excess of the 1-month Treasury-bill rate on the excess market return using a 36-month moving window, when at least 24 months of non-missing returns are available. We use the excess returns on the market factor available from Kenneth French's website. For each month, we also compute *Momentum* as the average individual stock return from month $t-12$ to $t-2$, as in Bessembinder et al (2019).

From Compustat, we also retrieve the following firm-level annual accounting characteristics: *Leverage* (long-term debt plus debt in current liabilities, divided by total assets, in percentage points: $(dltt + dlc) \times 100/at$), *Size* i.e. $\ln(\text{market cap})$ ($\ln(\text{prcc f} \times \text{csho})$), *Book-to-market* (book value of equity divided by market valuation: $\text{ceq}/(\text{prcc f} \times \text{csho})$), and *Profitability* (annual income before extraordinary items over total assets: $\text{ib} \times 100/at$).

We merge the above Compustat data with the firms' ESG scores from Sustainalytics, which are also employed in Engle et al.¹¹ To facilitate the economic interpretation of the results, we standardise the environmental scores from Sustainalytics to have mean of 0 and a unit standard deviation. As an alternative proxy for environmental responsibility, we compute the firms' environmental score using the MSCI KLD database.¹² Specifically, *ENV (kld)* is defined as the fraction of covered environmental "strengths" indicators equal to one minus the fraction of covered environmental "concerns" indicators equal to one, following a common practice in the ESG literature (eg Krüger (2015); Lins et al (2017)).

We end up with a sample of approximately 95,000 firm-month observations from January 2010 through June 2020 with available stock returns, accounting information and environmental score. Table 4 reports descriptive statistics of the main variables used in our analyses. We omit a detailed discussion of these statistics for the sake of brevity.

¹¹ Given that the Sustainalytics scores at our disposal are available for the period from 2010 through 2017, we expand the latest available score through June 2020, relying on the stickiness of ESG scores.

¹² The MSCI KLD data set, which we access through WRDS, provides a series of dummy variables indicating, for each firm and year, the presence of strengths or concerns on several environmental, social and governance factors.

3.2 Main results on stock returns

Table 5 reports the result of OLS regressions of individual stock returns on the interaction between the Green Sentiment Index and the firm's environmental score, as well as standard firm characteristics (*Leverage*, *Market beta*, *Log(market cap)*, *Book-to-market*, *Profitability* and *Momentum*).¹³ The regressions also include sector fixed effects based on the GICS industry group classification (comprising a total of 26 industries). We cluster standard errors at the firm level to control for the correlation of residuals within firms.¹⁴

¹³ We control for firm characteristics instead of a stock's estimated loadings on the size, value and quality factors following Kelly et al (2019) and Bessembinder et al (2019). However, we obtain very similar results when controlling for factor loadings instead of firm characteristics, or even using model-adjusted returns on the left-hand side of the regressions.

Green sentiment and the pricing of corporate environmental responsibility

Note: t-statistics based on standard errors clustered at the firm level are reported in parentheses. ***, **, and * indicate that the coefficient estimate is significantly different from zero at the 1%, 5%, and 10% level, respectively.

Source: authors' calculations.

The coefficient of interest is on the interaction between *Green sentiment* and the firm's environmental performance, *Env score*. We observe that, in months with a one standard deviation higher green sentiment, firms with a one standard deviation stronger environmental¹⁴ performance experience a 7 basis points higher return (Column 1 of Table 5). The effect is statistically significant, but economically small. We interpret this result as indicating that the pressure on the price of environmentally responsible shocks caused directly by green ETFs' arbitrage activity

¹⁴ As discussed in Section 3.5, our findings remain statistically significant even when double-clustering standard errors both at the firm and time dimensions (Petersen (2009); Thompson (2011)). We present our main results clustering at the firm level because, given the relatively short period analysed, clustering standard errors (also) at the time level risks to be excessively restrictive.

– a channel similar to the one documented in Ben-David et al (2018) – is, in our setting, limited. Indeed, not all environmentally responsible firms are included in green ETFs and hence directly affected by their arbitrage activity. We confirm this intuition in Section 3.4 by directly controlling for green ETFs’ ownership.

When looking at the effect in $t+1$ (column 2), we find that green sentiment predicts a strong outperformance associated with a firm’s environmental responsibility. A one standard deviation higher green sentiment leads to approximately 27 basis points per additional standard deviation of environmental responsibility. The effect is highly statistically significant.

Effect of Green Sentiment on the pricing of corporate environmental responsibility

Graph 3.1

Effect of one standard deviation higher green sentiment on the stock returns of firms with one standard deviation stronger environmental performance

Source: authors’ calculations.

Interestingly, the effect does not appear to revert in the following months (columns 3 to 7). It slightly increases in magnitude through $t+4$ and remains stable in $t+5$ and $t+6$. A one standard deviation higher green sentiment in t leads to an outperformance of one standard deviation more environmentally responsible firms approximately equal to 0.53% through $t+6$. Graph 3 illustrates the evolution of this effect using cumulative returns through $t+12$. Even when looking at such extended time frame, the stock price effect of green sentiment persists, with only a mild reversal.

One may have expected the stock price effects of green sentiment to be only temporary, as for other forms of investor sentiment (Baker and Wurgler (2006)). However, as also noticed in Pástor et al (2020), shifts in green tastes, although not driven by fundamental considerations, are likely to be persistent and, hence, drive a long-lasting effect on stock prices.

3.3 Green sentiment vs climate risk

We here conduct three tests further supporting the claim that the effect of green sentiment on the value of corporate climate responsibility is not driven by new fundamental environmentally related information.

First, in Table 6, we split the sample period before and after the Paris Agreement was signed in December 2015. Previous works document that the Paris Agreement significantly increased the salience and materiality of climate transition risks for institutional investors (Bolton and Kacperczyk (2022); Delis et al (2019); Seltzer et al (2021)). We expect the effect of green sentiment to be independent from such an important regulatory development. Table 6 shows that this is actually the case: green sentiment mediates the value of environmental responsibility both before and after the Paris Agreement.

Green sentiment and stock prices: before and after the Paris Agreement Table 6

Panel A: Before December 2015							
Dependent variable:	Return in t	Cumulative return through:					
		t+1	t+2	t+3	t+4	t+5	t+6
Green sentiment × Env score	0.093** (2.25)	0.428*** (7.08)	0.342*** (4.49)	0.628*** (7.10)	0.642*** (6.69)	0.506*** (4.93)	0.628*** (5.68)

Note: ***, **, and * indicate that the coefficient estimate is significantly different from zero at the 1%, 5%, and 10% level, respectively.

Source: authors' calculations.

Second, in Table 7 we re-run our regressions of individual stock returns by also including the interaction between the environmental score and the negative climate news index of Engle et al, aimed at capturing variation in (perceived) climate risk (the sample is reduced because Engle et al's measure is available only through May 2018). We find that, even when accounting for news-based climate risk, green sentiment is associated with a significant increase in the value of corporate environmental responsibility. We observe that the negative climate news measures has important effects on stock prices, in line with what documented by Engle et al. The results are particularly striking when recalling that *Green sentiment* and *Negative climate news* correlate negatively with each other (see Table 3), suggesting that they affect stock prices through different channels.

Green sentiment and stock prices: Accounting for negative climate news

Table 7

Dependent variable:	Return in t	Cumulative return through:

Note: t-statistics based on standard errors clustered at the firm level are reported in parentheses. ***, **, and * indicate that the coefficient estimate is significantly different from zero at the 1%, 5%, and 10% level, respectively.

Source: authors' calculations.

Third, we shift our attention from stock prices to analysts' earnings forecasts, which are meant to reflect changes in cash flows expectations (Brown and Rozeff (1978)). Although stock prices and forecast revisions are generally highly positively correlated (Kothari et al (2016)), we expect green sentiment to drive a divergence of the two dimensions, ie to cause an increase in stock prices that is not accompanied by a positive update of earnings forecasts. For this exercise, we retrieve data on earnings forecasts from the IBES Summary Statistics database, which provides snapshots as of the day before the third Friday of each month of individual firms' expected earnings per share (EPS) at different horizons. For each firm-month observation, we compute the monthly change in average earnings forecasts, ΔEPS forecast, at one-, two-, and three-year horizons as done, eg in Landier and Thesmar (2020).¹⁵

¹⁵ Specifically, for each horizon h and firm i , we compute the earnings revisions as $\Delta EPSForecast_{i,h} = E_{t+1}(EPS_{i,h}) - E_t(EPS_{i,h})$ scaled by 100, when $E_t(EPS_{i,h}) > 0$. We trim the resulting values at the 1st and 99th percentiles. The horizon is computed on the basis of the distance between the forecast's statistical period (variable "statpers") of the end date of the accounting period covered by the forecast (variable "fpedats"): one year (fiscal year ending between one and 12 months after the forecast's statistical period), two years (fiscal year ending between one and two years after the forecast's statistical period), three years (fiscal year ending between two and three years after the forecast's statistical period).

Green sentiment and analysts' forecast revisions Table 8

	(1)	(2)	(3)
Dependent variable:	Δ EPS forecast		
Horizon:	1-year ahead	2-year ahead	3-year ahead
Green sentiment \times Env score	-0.017 (-0.45)	-0.004 (-0.15)	0.048 (1.51)
Negative climate news \times Env score	0.032 (1.06)	0.066*** (2.79)	0.064** (2.52)
Env score	-0.116 (-1.56)	-0.067 (-1.18)	-0.072 (-1.43)
Observations	61,055	62,102	58,608
R-squared	0.026	0.045	0.035
Firm controls	Yes	Yes	Yes
Industry FE	Yes	Yes	Yes
Month FE	Yes	Yes	Yes

Note: t-statistics based on standard errors clustered at the firm level are reported in parentheses. ***, **, and * indicate that the coefficient estimate is significantly different from zero at the 1%, 5%, and 10% level, respectively.

Source: authors' calculations.

Table 8 shows the results of OLS regressions of forecast revisions between months t and $t+1$ on green sentiment in month t interacted with firms' environmental scores, controlling for firm characteristics, as well as sector and month fixed effects. The regressions also include the interaction between the environmental score and Engle et al's negative climate news index. As expected, green sentiment does not appear to have any explanatory power on the revisions of earnings forecasts, despite its effects on stock returns. Conversely, the Engle et al negative climate news index is associated with a statistically significant increase in the average forecast at the two-year and three-year horizons.

3.4 Green sentiment vs. ETF price pressure

Throughout the paper, we use the observed abnormal flows into green ETFs as a proxy for market-wide green sentiment. In particular, we argue that the observed stock price effect of green sentiment is the result of changes in investor appetite for environmental responsibilities, and not merely of the price pressure exerted directly by the ETF arbitrage activity, the propagation mechanism identified by Ben-David et al (2018).

To rule out the possibility that our results are mechanically driven by (green) ETFs' arbitrage activity, in Table 9, we replicate our main regressions by interacting the green sentiment index also with the percentage of common stocks held by green ETFs (*Green ETF ownership*). To compute this variable, we first retrieve green ETFs' portfolio holdings from the CRSP survivor-bias-free US mutual fund database. For each stock-month observation, we then divide the sum of green ETFs holdings in USD over the total market capitalisation.

Green sentiment and direct price pressure from green ETFs Table 9

Dependent variable:	Return in t	Cumulative return through

Source: authors' calculations.

Green sentiment does not appear to predict any stock return effect on green ETFs' constituents, at least not over our sample period. On the contrary, green sentiment continues to have a significant predictive power on the pricing of environmental responsibility, in line with our main results.

3.5 Additional robustness checks

This subsection investigates the robustness of the stock price effects of green sentiment in four relevant dimensions.

First, Appendix Table A1 shows that our estimates remain statistically significant even when we double-cluster standard errors at the firm and the month levels to allow for potential correlation of residuals across both dimensions (Petersen (2009); Thompson (2011)).¹⁶

Second, Appendix Table A2 shows that our results are robust to including month fixed effects, to account for potential effect of macroeconomic conditions on

¹⁶ With this double-clustering, the specification nests the classical Fama-MacBeth procedure (Fama and MacBeth (1967)) which controls for time effect in the correlation of residuals, but not for potential firm effect.

the pricing of environmental responsibility.¹⁷ Notice that in these regressions the direct effect of *Green sentiment* is absorbed by the month indicators.

Third, given the diffuse concerns on the disagreement between ESG scores from different providers (Berg et al (2022); Gibson et al (2021)), in Appendix Table A3 we replicate our results using the alternative definition of environmental responsibility based on the MSCI KLD data set (*Env score (kld)*).¹⁸ Note that in these regressions the sample is considerably larger given the broader coverage offered by the MSCI KLD database. Despite these differences, we obtain regression estimates that are statistically and economically similar to the ones obtained with our main proxy of environmental responsibility.

4. Effects of green sentiment on corporate behaviour

One of the most common narratives in the ESG industry is that sustainable investing can trigger positive societal change by influencing a firm's cost of capital, which in turn should allow more socially responsible firms to make more and better investments than other firms.

The above "financing channel mechanism" of responsible investing is identified and discussed in several theoretical works (Heinkel et al (2001); Pástor et al (2020); Oehmke and Opp (2020); Landier and Lovo (2020); De Angelis et al (2020)), but related empirical evidence remains scarce. In this section, we exploit the properties of our ETF-based Green Sentiment Index to shed light on the effects of investor non-fundamental demand shocks for green assets on corporate behaviour.

4.1 Main results on corporate behaviour

We focus on two important corporate decisions: investment and saving, by examining the impact of green sentiment on the levels of capital investments and cash holdings, which are useful for precautionary (Bates et al (2009); Almeida et al (2014)) and repurchase (Wang and Nyborg (2021)) motives, as well as to finance future investment (Bolton et al (2013)).

Based on the Compustat Accounting Quarterly database, we compute the variable *Capex/PPE* as the percentage of capital investments scaled by lagged Property, Plant and Equipment ($\text{capexq} \times 100 / \text{L1.ppentq}$), the variable *Cash/Assets* as the percentage of cash holdings over total assets ($\text{chq} \times 100 / \text{atq}$), and the variable *R&D/Assets* as the percentage of research and development expenses over total assets ($\text{xrdq} \times 100 / \text{atq}$).¹⁹ We trim these variables at the 1–99 percentiles to control for extreme values. For the purposes of this analysis, we bring our data from the monthly

¹⁷ For instance, Bansal et al (2018) argue that stocks of socially responsible firms outperform in good economic times, whereas Lins et al (2017) and Albuquerque et al (2020) provide evidence that stocks of socially responsible firms performance relatively well in crisis times.

¹⁸ In our sample, the environmental scores from Sustainalytics and from MSCI KLD have a correlation of .58, statistically significant at the 1% level.

¹⁹ We normalise capex by lagged property, plant and equipment following Dessaint et al (2019). However, our results are robust to normalising capex by lagged total assets.

to the quarterly level. Summary statistics on *Capex/PPE*, *Cash/Assets*, and *R&D/Assets* are reported in Table 4.

In Table 10, we report the results of OLS regressions of quarterly capex (column 1), cashholdings (column 2), and R&D (column 3) on the average quarterly green sentiment, the firm's environmental score, and the interaction of the two. The regressions also control for firm characteristics and sector fixed effects (we obtain similar results when also adding quarter fixed effects, absorbing the direct effect of the green sentiment index). Standard errors are clustered at the firm level to account for the correlation of error terms across firms.²⁰

Source: authors' calculations.

The results indicate that higher green sentiment in a given quarter is associated with higher capital investments and accumulation of cash for more environmentally responsible firms, consistent with the idea that firms make more investments and hold larger cash balances when access to funds is easier (eg Dittmar et al (2003)). The effect is economically important: a one standard deviation stronger green sentiment is associated with 0.21% higher capex and 0.31% higher cash holdings for a one

²⁰ The estimated coefficients remain statistically significant even if we double-cluster standard errors at both the firm and quarter levels (Petersen (2009); Thompson (2011)).

standard deviation higher environmental score (compared with an average capex of 9% and cash holdings of 4%, this represents respectively a 5% and 3% relative increase). We do not observe any effect of green sentiment on green firms' R&D activity.

4.2 Heterogeneity across credit ratings

What types of firm is green sentiment more likely to influence? The existing literature suggests that managers of more equity-dependent/credit-constrained firms are more likely to be influenced by stock prices in their decision-making (Baker et al (2003); Hau and Lai (2013)). We expect this principle to apply also in the context of the real impacts of responsible investing. Intuitively, the effects of green sentiment on corporate decisions should vary with a firm's ability to raise funds outside the stock market.²¹

To test for the heterogeneity of the effect of green sentiment on real corporate decisions, we split our sample on the basis of corporate credit ratings, which we use as a proxy of the firm's ability to access external capital on credit markets. We retrieve corporate long-term S&P credit ratings from Bloomberg, and we classify them in three groups: *Low credit rating* < "BBB-" (non-investment grade); *Middle credit rating* = "BBB", "BBB+", "BBB-"; *High credit rating* = "A", "A+", "A-", "AA", "AAA", "AA-", "AA+".

Table A4 in the Appendix shows the number of firms × quarters with above- and below-median environmental score in each of the three credit rating groups. Not surprisingly, we observe a positive correlation between environmental responsibility and credit ratings, consistent with the evidence in Seltzer et al (2021). For instance, we find that firms with a high environmental score have a likelihood of 34% to also have a high credit rating, versus only 16% among firms with low environmental score.²²

Table 11 shows the heterogeneity of the effects of green sentiment on firm behaviour along the credit rating. We obtain two intriguing results. First, in Panel A, we show that the effect of green sentiment on capital investment is concentrated in firms with low and medium credit ratings. No significant effect is observed for companies with a strong credit rating. This result is consistent with the idea that less equity-dependent firms are less influenced by stock prices in making investment decisions (Baker et al (2003)). Our results indicate that these firms are also less likely to be influenced by green sentiment. Second, in Panel B, we observe that the effect of green sentiment on cash holdings is driven primarily by the subsamples of low- (and to a less extent) highly rated firms, consistent with the idea that cash holdings are more valuable for financially constrained firms (Denis and Sibilkov (2010)). Conceivably, these firms take advantage of green sentiment to increase their precautionary buffers.

²¹ For instance, the model in Landier and Lovo (2020) suggests that, in order for ESG funds to force companies to partially internalise externalities, it is necessary to have significant frictions in financial markets.

²² Indeed, the environmental score even correlates positively with the likelihood of having the credit rating available in the first place, causing Table A4 to show relatively more firms with an above-median environmental score.

5. Conclusion

In the past decade, environmental considerations have taken centre stage in shaping the debate in global financial markets, a trend that is set to continue for many years to come. How do changes in investors' appetite for green assets influence the allocation of capital in the economy and the behaviour of firms? This question is a key policy issue, as many policymakers and regulators expect the redirection of capital market financing towards green firms to have a decisive impact on carbon emissions (eg Lagarde (2021)) and firms' cost of capital (eg Scatigna et al (2021)).

Studying the effects of investors' environmental preferences on economic outcomes is an empirical challenge due to the entanglement of fundamental and non-fundamental factors in driving firm value. In this paper, we proposed a new method for estimating non-fundamental demand shocks for green financial assets. The method exploits the unique arbitrage mechanism of ETFs' primary market, which the existing literature shows to be influenced by non-fundamental demand shocks due to differences in the ownership structure of ETFs compared with the underlying securities (Ben-David et al (2017); Brown et al (2023)). Specifically, using a

comprehensive sample of US ETFs over the period from January 2010 through June 2020, we estimate the monthly excess flows into ETFs with explicit environmentally friendly features (green ETFs) relative to comparable conventional ETFs. The time series of these abnormal green flows – which we name the Green Sentiment Index – quantifies the direction and magnitude of changes in investors’ appetite for green financial assets that are not priced in the value of the underlying securities.

After establishing the difference between our index and other climate-related measures used in the literature, we study the effects of green sentiment on the pricing of corporate environmental responsibility in the stock market and on corporate decisions. Using a sample of US firms over the period January 2010 to June 2020, we establish two key results.

First, we show that higher green sentiment is associated with a stock price outperformance of environmentally responsible firms. A one standard deviation stronger green sentiment in month t is followed by approximately 27 basis points higher returns in $t+1$ for a one standard deviation higher environmental score. The estimated outperformance considering returns through in $t+6$ is 53 basis points. A series of tests confirm that this effect does not reflect fundamental information: green sentiment predicts stock prices both before and after the signature of the Paris Agreement, a structural break in climate transition risks; its stock price effects are independent to variations in climate risk, as proxied by the negative climate news index used in Engle et al; finally, despite the fact that they both have similar stock price effects, Engle et al’s index leads to positive revisions in analysts’ earnings forecasts for environmentally responsible firms, while our green sentiment index does not.

Second, we document that an increase in green sentiment also affects corporate decisions. In quarters with strong green sentiment, environmentally responsible firms make higher capital investments (particularly firms with low and medium credit ratings) and accumulate more cash holdings (particularly firms with low and high credit ratings). The role of financial constraints in mediating the impact of (green) sentiment on corporate behaviour is in line with previous works on the real effects of financial markets (eg Baker et al (2003); Campello and Graham (2013)) and the theoretical literature on responsible investing. It is reasonable to expect that companies are more likely to do “good” when they are less financially constrained (Cohn and Wardlaw (2016); Hong et al (2012); Martin et al (2021)). In this sense, by (further) increasing the financial strength of environmentally responsible firms, green sentiment allows them to further increase their environmentally friendly investments. At the same time, we should also be aware of the risk that green sentiment may inadvertently divert resources away from firms that are not currently considered green but have high green innovation potential (Cohen et al (2020)).

How to encourage firms to contribute to the development of technologies useful to decarbonise our economies is a key question of our times.²³ While the effects of governmental policies (such as carbon pricing) and the role of public finance are more researched and understood (eg Aghion et al (2016); Gollier (2021)), the role of financial markets in stimulating firms to make more investments in green projects and technologies deserves investigation. Our results suggest that green sentiment

²³ Almost half of the emission reductions that are needed to reach the climate-neutrality goal by 2050 are expected to come from technologies that still need to be developed (International Energy Agency (2021)).

can reduce the relative cost of capital of more environmentally responsible firms, and increase their investment capacity. How exactly firms make use of these extra resources is a critical issue that we leave for future research.
